

## Probabilistic Inference

In artificial intelligence, we often want to model the relationships between various nondeterministic events. If the weather predicts a 40% chance of rain, should I carry my umbrella? How many scoops of ice cream should I get if the more scoops I get, the more likely I am to drop it all? If there was an accident 15 minutes ago on the freeway on my route to Oracle Arena to watch the Warriors' game, should I leave now or in 30 minutes? All of these questions (and innumerable more) can be answered with **Probabilistic Inference**.

We're assuming that you've learned the foundations of probability in CS70, so these notes will not review basic concepts of probability like PDFs, conditional probabilities, independence, and conditional independence.

In previous sections of this class, we modeled the world as existing in a specific state that is always known. For the next several weeks, we will instead use a new model where each possible state for the universe has its own probability. For example, we might build a weather model, where the state consists of the season, temperature and weather. Our model might say that  $P(\text{winter}, 35^\circ, \text{cloudy}) = 0.00023$ . This number represents the probability of the specific outcome that it is winter, 35 degrees, and cloudy.

More precisely, our model is a **joint distribution**, i.e. a table of probabilities which captures the likelihood of each possible **outcome**, also known as an **assignment**. As an example, consider the table below:

Season	Temperature	Weather	Probability
summer	hot	sun	0.30
summer	hot	rain	0.05
summer	cold	sun	0.10
summer	cold	rain	0.05
winter	hot	sun	0.10
winter	hot	rain	0.05
winter	cold	sun	0.15
winter	cold	rain	0.20

This model allows us to answer questions that might be of interest to us, for example:

- What is the probability that it is sunny?  $P(W = \text{sun})$
- What is the probability distribution for the weather, given that we know it is winter?  $P(W \mid S = \text{winter})$
- What is the probability that it is winter, given that we know it is rainy and cold?  $P(S = \text{winter} \mid T = \text{cold}, W = \text{rain})$
- What is the probability distribution for the weather and season given that we know that it is cold?  $P(S, W \mid T = \text{cold})$

Given a joint PDF, we can trivially perform compute any desired probability  $P(Q_1 \dots Q_k \mid e_1 \dots e_k)$  using a simple intuitive procedure known as **Inference by Enumeration**. In this procedure, we collect all the rows consistent with the evidence available (i.e.  $e_1 \dots e_k$ , sum out all the hidden variables (i.e. all variables for which we do not have evidence), and finally normalize the table so that it is a probability distribution (i.e. values sum to 1).

For example, if we wanted to compute  $P(W \mid S = \text{winter})$ , we'd select the four rows where S is winter, then sum out the T variable and normalize, yielding the two row table where  $P(W = \text{sun} \mid S = \text{winter}) = 0.5$  and  $P(W = \text{rain} \mid S = \text{winter}) = 0.5$ .

So long as we have the joint PDF table, inference by enumeration (IBE) can be used to compute any desired probability, even for multiple query variables  $Q_1 \dots Q_k$ .

## Bayes Nets (Representation)

While IBE can compute probabilities for any query we might desire, representing an entire joint distribution in the memory of a computer is impractical for real problems - if each of  $n$  variable we wish to represent can take on  $d$  possible values (it has a **domain** of size  $d$ ), then our joint distribution table will have  $d^n$  entries!

Bayes nets avoid this issue by taking advantage of the idea of conditional probability. Rather than storing information in a giant table, it is instead distributed across a large number of smaller local probability tables along with a **directed acyclic graph** which captures the relationships between variables.

Specifically, each node in the graph represents a single random variable. Arrows in the graph represent conditional probability distributions. **A node is conditionally independent of all its ancestor nodes in the graph, given all of its parents.** Thus, if we have a node representing variable Q, we store  $P(Q \mid X_1, X_2, \dots, X_N)$ , where  $X_1, \dots, X_N$  are the parents of Q.

As an example of a Bayes Net, consider a model where we have five binary random variables described below:

- B: Burglary occurs.
- A: Alarm goes off.
- E: Earthquake occurs.
- J: John calls.
- M: Mary calls.

Assume the alarm can go off if either a burglary or an earthquake occurs, and that Mary and John will call if they hear the alarm. We can represent these dependencies with the graph shown below.

Models capture a way the world works - they are always a simplification - all models are wrong, but some will still be useful for solving real problems in the real world. They may may not account for every variable or even every interaction between variables.

More formally, we say that a Bayes Net consists of:

- A directed acyclic graph of nodes, one per variable  $X$ .
- A conditional distribution for each node  $P(X|A_1 \dots A_n)$ , where  $A_i$  is the  $i$ th parent of  $X$ , stored as a **conditional probability table** or CPT. Each CPT has  $n + 1$  columns: one containing values for each parent variable  $A_1 \dots A_n$ , and one for the conditional probability of  $X$ .

For example, for the alarm model above, we would have probability tables  $P(B), P(E), P(A | B, E), P(J | A)$  and  $P(M | A)$ .

Given all of the CPTs for a graph, we can calculate the probability of a given assignment using the chain rule:  $P(X_1, X_2, \dots, X_n) = \prod_{i=1}^n P(X_i | \text{parents}(X_i))$ .

For the alarm model above, we might calculate the probability of one event as follows:  $P(-b, -e, +a, +j, -m) = P(-b) \cdot P(-e) \cdot P(+a | -b, -e) \cdot P(+j | +a) \cdot P(-m | +a)$ .

This works because of the conditional independence relationships given by the graph. Specifically, we rely on the fact that  $P(x_i | x_1, \dots, x_{i-1}) = P(x_i | \text{parents}(X_i))$ . Or in other words, that the probability of a specific value of  $X_i$  depends only on the values assigned to  $X_i$ 's parents.

## Bayes Nets (Inference)

Inference is the process of calculating the joint PDF for some set of query variables based on some set of observed variables. We can solve this problem naively by forming the joint PDF and using Inference by Enumeration as described above. This requires creation and iteration over an exponentially large table.

An alternate approach is to **eliminate** variables one by one. To eliminate a variable  $X$ , we:

- Join (multiply together) all factors involving  $X$ .

- Sum out X.

For example, suppose we have a model as shown below, where T, C, S, and E can take on binary values, as shown below. Here, T represents the chance that an adventurer takes a treasure, C represents the chance that a cage falls on the adventurer given that he takes the treasure, S represents the chance that snakes are released if an adventurer takes the treasure, and E represents the chance that the adventurer escapes given information about the status of the cage and snakes.

In this case, we have the factors  $P(T)$ ,  $P(C|T)$ ,  $P(S|T)$ , and  $P(E|C,S)$ . Suppose we want to calculate  $P(T|+e)$ . The Inference by Enumeration approach would be to form the 16 row joint PDF  $P(T,C,S,E)$ , select only the rows corresponding to  $+e$ , then summing out C and S and finally normalizing.

The alternate approach is to eliminate C, then S, one variable at a time. We'd proceed as follows:

- Join (multiply) all the factors involving C, forming  $P(C, +e|T, S) = P(C|T) \cdot P(+e|C, S)$ .
- Sum out C from this new factor, leaving us with a new factor  $P(+e|T, S)$ .
- Join all factors involving S, forming  $P(+e, S|T) = P(S|T) \cdot P(+e|T, S)$ .
- Sum out S, yielding  $P(+e|T)$ .

Once we have  $P(+e|T)$ , we can easily compute  $P(T|+e)$ . For a more thorough working out of the example, see lecture 15.

While this process is more involved from a conceptual point of view, the maximum size of any factor generated is only 8 rows instead of 16 as it would be if we formed the entire joint PDF.

An alternate way of looking at the problem is to observe that the calculation of  $P(+e, T)$  can either be done, as it is in Inference by Enumeration, as follows:

$$\sum_s \sum_c P(T)P(s|T)P(c|T)P(+e|c,s)$$

Variable elimination is equivalent to calculating  $P(+e, T)$  as follows:

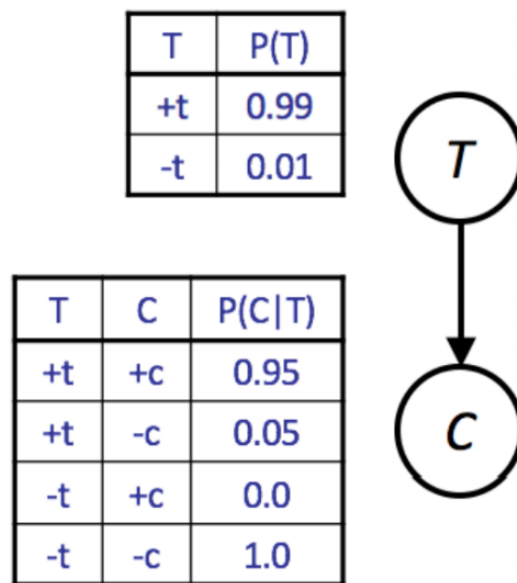

$$P(T) \sum_s P(s|T) \sum_c P(c|T)P(+e|c,s)$$

# Bayes Nets (Sampling)

An alternate approach for probabilistic reasoning is to implicitly calculate the probabilities for our query by simply counting samples.

For example, suppose we wanted to calculate  $P(T|+e)$ . If we had a magic machine that could generate samples from our distribution, we could collect all samples for which the adventurer escapes the maze, and then compute the fraction of those escapes for which the adventurer also took the treasure. Put differently, if we could run simulations of say, million of adventurers, we'd easily be able to compute any inference we'd want just by looking at the samples.

Given a Bayes Net model, we can easily write a simulator. For example, consider the CPTs given below for the simplified model with only two variables  $T$  and  $C$ .

A simple simulator in Python would be as follows:

```
import random

def get_t():
    if random.random() < 0.99:
        return True
    return False

def get_c(t):
    if t and random.random() < 0.95:
        return True
    return False

def get_sample():
```

```

t = get_t()
c = get_c(t)
return [t, c]

```

We call this simple approach **prior sampling**. The downside of this approach is that it may require the generation of a very large number of samples in order to perform analysis of unlikely scenarios. If we wanted to compute  $P(C|t)$ , we'd have to throw away 99% of our samples.

One way to mitigate this problem, we can modify our procedure to early reject any sample inconsistent with our evidence. For example, for the query  $P(C|t)$ , we'd avoid generating a value for  $C$  unless  $t$  is true. This still means we have to throw away most of our samples, but at least the bad samples we generate take less time to create. We call this approach **rejection sampling**.

These two approaches work for the same reason, which is that any valid sample occurs with the same probability as specified in the joint PDF. In other words, the probability of every sample is based on the product of every CPT, or as I personally call it, the "every CPT participates principle".

A more exotic approach is **likelihood weighting**, which ensures that we never generate a bad sample. In this approach, we manually set all variables equal to the evidence in our query. For example, if we wanted to compute  $P(C|t)$ , we'd simply declare that  $t$  is false. The problem here is that this may yield samples that are inconsistent with the correct distribution. As an example, consider the more complex four variable model for  $T$ ,  $C$ ,  $S$ , and  $E$  given earlier in these notes. If we wanted to compute  $P(T, S, +c, +e)$ , and simply picked values for  $T$  and  $S$  without taking into account the fact that  $c = \text{false}$ , and  $e = \text{true}$ , then there's no guarantee that our samples actually obey the joint PDF given by the Bayes Net. For example, if the cage only ever falls if the treasure is taken, then we'd want to ensure that  $T$  is always true instead of using the  $P(T)$  distribution given in the Bayes Net.

Put differently, if we simply force some variables equal to the evidence, then our samples occur with probability given only equal to the products of the CPTs of the non-evidence variables. This means the joint PDF has no guarantee of being correct (though may be for some cases like our two variable Bayes Net). Instead, if we have sampled variables  $Z_1$  through  $Z_p$  and fixed evidence variables  $E_1$  through  $E_m$  a sample is given by the probability  $P(Z_1 \dots Z_p, E_1 \dots E_m) = \prod_i P(Z_i | \text{Parents}(Z_i))$ . What is missing is that the probability of a sample does not include all the probabilities of  $P(E_i | \text{Parents}(E_i))$ , i.e. not every CPT participates.

Likelihood weighting solves this issue by using a weight for each sample, which is the probability of the evidence variables given the sampled variables. That is, instead of counting all samples equally, we can define a weight  $w_j$  for sample  $j$  that reflects how likely the observed values for the evidence variables are, given the sampled values. In this way, we ensure that every CPT participates. To do this, we iterate through each variable in the Bayes net, as we do for normal sampling, sampling a value if the variable is not an evidence variable, or changing the weight for the sample if the variable is evidence.

For example, suppose we want to calculate  $P(T|+c, +e)$ . For the  $j$ th sample, we'd perform the following algorithm:

- Set  $w_j$  to 1.0, and  $c = \text{true}$  and  $e = \text{true}$ .
- For  $T$ : This is not an evidence variable, so we sample  $t_j$  from  $P(T)$ .
- For  $C$ : This is an evidence variable, so we multiply the weight of the sample by  $P(+c|t_j)$ , i.e.  $w_j = w_j \cdot P(+c|t_j)$ .
- For  $S$ : sample  $s_j$  from  $P(S|t_j)$ .

- For  $E$ : multiply the weight of the sample by  $P(+e|+c,s_j)$ , i.e.  $w_j = w_j \cdot P(+e|+c,s_j)$ .

Then when we perform the usual counting process, we weight sample  $j$  by  $w_j$  instead of 1, where  $0 \leq w_j \leq 1$ . This approach works because in the final calculations for the probabilities, the weights effectively serve to replace the missing CPTs. In effect, we ensure that the weighted probability of each sample is given by  $P(z_1 \dots z_p, e_1 \dots e_m) = [\prod_i^p P(z_i | Parents(z_i))] \cdot [\prod_i^m P(e_i | Parents(e_i))]$ .

For all three of our sampling methods (prior sampling, rejection sampling, and likelihood weighting), we can get increasing amounts of accuracy by generating additional samples. However, of the three, likelihood weighting is the most computationally efficient, for reasons beyond the scope of this course.

Gibbs Sampling is a fourth approach for sampling. In this approach, we first set all variables to some totally random value (not taking into account any CPTs). We then repeatedly pick one variable at a time, clear its value, and resample it given the values currently assigned to all other variables.

For the  $T, C, S, E$  example above, we might assign  $t = \text{true}$ ,  $c = \text{true}$ ,  $s = \text{false}$ , and  $e = \text{true}$ . We then pick one of our four variables to resample, say  $S$ , and clear it. We then pick a new variable from the distribution  $P(S|+t, +c, +e)$ . This requires us knowing this conditional distribution. It turns out that we can easily compute the distribution of any single variable given all other variables. More specifically,  $P(S|T, C, E)$  can be calculated only using the CPTs that connect  $S$  with its neighbors. Thus, in a typical Bayes Net, where most variables have only a small number of neighbors, we can precompute the conditional distributions for each variable given all of its neighbors in linear time.

We will not prove this, but if we repeat this process enough times, our later samples will eventually converge to the correct distribution even though we may start from a low-probability assignment of values. If you're curious, there are some caveats beyond the scope of the course that you can read about under the Failure Modes section of the Wikipedia article for Gibbs Sampling.

## Bayes Nets (D-Separation)

One useful question to ask about a set of random variables is whether or not one variable is independent from another, or if one random variable is conditionally independent of another given a third random variable. Bayes' Nets representation of joint probability distributions gives us a way to quickly answer such questions by inspecting the topological structure of the graph.

We already mentioned that **a node is conditionally independent of all its ancestor nodes in the graph given all of its parents.**

We will present all 3 canonical cases of connected 3-node 2-edge Bayes' Nets, or triples, and the conditional independence relationships they express.

### Causal Chains

Figure 1: Causal Chain with no observations.

Figure 2: Causal Chain with  $Y$  observed.

Figure 1 is a causal chain. It expresses the following representation of the joint distribution over  $X$ ,  $Y$ , and  $Z$ :

$$P(x, y, z) = P(z|y)P(y|x)P(x) \quad (1)$$

We note that  $X$  and  $Z$  are not guaranteed to be independent as one can construct a counter example distribution:

$$P(y|x) = \begin{cases} 1 & \text{if } x = y \\ 0 & \text{else} \end{cases} \quad P(z|y) = \begin{cases} 1 & \text{if } z = y \\ 0 & \text{else} \end{cases}$$

Then  $P(z|x) = 1$  if  $x = z$  and 0 otherwise, so  $X$  and  $Z$  are not independent.

However, we can make the statement that  $X \perp\!\!\!\perp Z \mid Y$ , as in Figure 2. Recall that this conditional independence means:

$$P(X|Z, Y) = P(X|Y) \quad (2)$$

We can prove this statement as follows:

$$P(X|Z, y) = \frac{P(X, Z, y)}{P(Z, y)} \quad (3)$$

$$= \frac{P(Z|y)P(y|X)P(X)}{\sum_x P(X, y, Z)} \quad (4)$$

$$= \frac{P(Z|y)P(y|X)P(X)}{P(Z|y) \sum_x P(y|x)P(x)} \quad (5)$$

$$= \frac{P(y|X)P(X)}{\sum_x P(y|x)P(x)} \quad (6)$$

$$= \frac{P(y|X)P(X)}{P(y)} \quad (7)$$

$$= P(X|y) \quad (8)$$

A general proof can be given for the case of  $X$  having multiple parents. To summarize, in the causal chain configuration,  $X \perp\!\!\!\perp Z \mid Y$ .

## Common Cause

Another possible configuration for a triple is the Common Cause (Figure 3). It expresses the representation:

$$P(x, y, z) = P(x|y)P(z|y)P(y) \quad (9)$$

$X$  is not guaranteed to be independent of  $Z$  by the following counterexample distribution:

$$P(x|y) = \begin{cases} 1 & \text{if } x = y \\ 0 & \text{else} \end{cases} \quad P(z|y) = \begin{cases} 1 & \text{if } z = y \\ 0 & \text{else} \end{cases}$$

Then  $P(x|z) = 1$  if  $x = z$  and 0 otherwise, so  $X$  and  $Z$  are not independent.

But it is true that  $X \perp\!\!\!\perp Z \mid Y$ , that is,  $X$  and  $Z$  are independent if  $Y$  is observed as in Figure 4. To show this:

$$P(X|Z, y) = \frac{P(X|y)P(Z|y)P(y)}{P(Z|y)P(y)} \quad (10)$$

$$= P(X|y) \quad (11)$$

Figure 3: Common Cause with no observations.

Figure 4: Common Cause with  $Y$  observed.

## Common Effect

The final possible configuration for a triple is the Common Effect in Figure 5.

Figure 5: Common Effect with no observations.

Figure 6: Common Effect with  $Y$  observed.

It expresses the representation:

$$P(x, y, z) = P(y|x)P(x)P(y|z)P(z) \quad (12)$$

In the configuration shown in Figure 5,  $X$  and  $Z$  are independent:  $X \perp\!\!\!\perp Z$ . However, they are not necessarily independent when conditioned on  $Y$  (Figure 6). As an example, suppose all three are binary variables.  $X$  and  $Z$  are true and false with equal probability:

$$P(X = \text{true}) = P(X = \text{false}) = 0.5 \quad (13)$$

$$P(Z = \text{true}) = P(Z = \text{false}) = 0.5 \quad (14)$$

and  $Y$  is determined by whether  $X$  and  $Z$  have the same value:

$$P(Y|X, Z) = \begin{cases} 1 & \text{if } X = Z \text{ and } Y = \text{true} \\ 1 & \text{if } X \neq Z \text{ and } Y = \text{false} \\ 0 & \text{else} \end{cases} \quad (15)$$

Then  $X$  and  $Z$  are independent if  $Y$  is unobserved. But if  $Y$  is observed, then knowing  $X$  will tell us the value of  $Z$ , and vice-versa. So  $X$  and  $Z$  are *not* conditionally independent given  $Y$ .

Common Effect can be viewed as “backwards” of Causal Chains and Common Cause –  $X$  and  $Z$  are guaranteed to be independent if  $Y$  is not conditioned on. But, conditioned on  $Y$ ,  $X$  and  $Z$  may be dependent (whether they are dependent or not depends on the specific probability values for  $P(Y | X, Z)$ ).

This same logic applies when conditioning on descendants of  $Y$  in the graph. If one of  $Y$ ’s descendent nodes is observed, as in Figure 7,  $X$  and  $Z$  are not guaranteed to be independent.

Figure 7: Common Effect with child observations.

## General Case, and D-separation

We can use the previous three cases as building blocks to help us answer conditional independence questions on an arbitrary Bayes’ Net with more than three nodes and two edges. We formulate the problem as follows:

**Given a Bayes Net  $G$ , two nodes  $X$  and  $Y$ , and a set of nodes  $\{Z_1, \dots, Z_k\}$  that represent observed variables, must the following statement be true:  $X \perp\!\!\!\perp Y | \{Z_1, \dots, Z_k\}$ ?**

(note that we can also have the case where the observed set is empty, i.e.  $k = 0$ )

**D-separation** (directed separation) is a property of the structure of the Bayes Net graph that implies this conditional independence relationship, and generalizes the cases we’ve seen above. If a set of variables  $Z_1, \dots, Z_k$  d-separates  $X$  and  $Y$ , then  $X \perp\!\!\!\perp Y | Z_1, \dots, Z_k$  in all possible distributions that can be encoded by the Bayes net.

We start with an algorithm that is based on a notion of reachability from node  $X$  to node  $Y$ . (**Note: this algorithm is not quite correct! We’ll see how to fix it in a moment.**)

1. Shade all observed nodes  $\{Z_1, \dots, Z_k\}$  in the graph.
2. If there exists an undirected path from  $X$  and  $Y$  that is not blocked by a shaded node,  $X$  and  $Y$  are “connected”.
3. If  $X$  and  $Y$  are connected, they’re not conditionally independent given  $\{Z_1, \dots, Z_k\}$ . Otherwise, they are.

However, this algorithm only works if the Bayes’ Net has no “Common Effect” structure within the graph,

because if it exists, then two nodes are “reachable” when the  $Y$  node in Common Effect is activated (observed). To adjust for this, we arrive at the following **d-separation algorithm**:

1. Shade all observed nodes  $\{Z_1, \dots, Z_k\}$  in the graph.
2. Enumerate all undirected paths from  $X$  to  $Y$ .
3. For each path:
  - (a) Decompose the path into triples (segments of 3 nodes).
  - (b) If all triples are active, this path is active and *d-connects*  $X$  to  $Y$ .
4. If no path d-connects  $X$  and  $Y$ , then  $X$  and  $Y$  are d-separated, so they are conditionally independent given  $\{Z_1, \dots, Z_k\}$

Any path in a graph from  $X$  to  $Y$  can be decomposed into a set of 3 consecutive nodes and 2 edges - each of which is called a triple. A triple is active or inactive depending on whether or not the middle node is observed. If all triples in a path is active, then the path is active and *d-connects*  $X$  to  $Y$ , meaning  $X$  is not guaranteed to be conditionally independent of  $Y$  given the observed nodes. If all paths from  $X$  to  $Y$  are inactive, then  $X$  and  $Y$  are conditionally independent given the observed nodes.

**Active triples:** We can enumerate all possibilities of active and inactive triples using the three canonical graphs we presented above in Figure 8 and 9.

Figure 8: Active triples

Figure 9: Inactive triples

## Examples

Here are some examples of applying the D-Separation algorithm:

This graph contains the common effect and causal chain canonical graphs.

- a)  $R \perp\!\!\!\perp B$  – Guaranteed
- b)  $R \perp\!\!\!\perp B \mid T$  – Not guaranteed
- c)  $R \perp\!\!\!\perp B \mid T'$  – Not guaranteed
- d)  $R \perp\!\!\!\perp T' \mid T$  – Guaranteed

This graph contains combinations of all three canonical graphs (can you list them all?).

- a)  $L \perp\!\!\!\perp T' \mid T$  – Guaranteed
- b)  $L \perp\!\!\!\perp B$  – Guaranteed
- c)  $L \perp\!\!\!\perp B \mid T$  – Not guaranteed
- d)  $L \perp\!\!\!\perp B \mid T'$  – Not guaranteed
- e)  $L \perp\!\!\!\perp B \mid T, R$  – Guaranteed

This graph contains combinations of all three canonical graphs.

- a)  $T \perp\!\!\!\perp D$  – Not guaranteed
- b)  $T \perp\!\!\!\perp D \mid R$  – Guaranteed
- c)  $T \perp\!\!\!\perp D \mid R, S$  – Not guaranteed

## Conclusion

To summarize, Bayes' Nets is a powerful representation of joint probability distributions. Its topological structure encodes independence and conditional independence relationships, and we can use it to model arbitrary distributions to perform inference and sampling.
